

☑ : This is a video of knot manipulation. Please determine whether the knot is a slip knot (can be undone by pulling one end) or a fixed knot (cannot be undone and remains tight when pulled). Answer Slip or Fixed.

✦ : Identifying Knot Type. I'm currently analyzing the initial stages of the knot being formed. My focus is on distinguishing whether it's a slip knot or a fixed knot by observing how the rope is manipulated around the bar. Confirming Slip Knot Mechanics. I've confirmed through detailed observation that the presented knot-tying action clearly demonstrates the defining characteristic of a slip knot. Specifically, the ability to completely undo the knot by pulling on the working end, as shown at the 00:16 and 00:23-00:25 marks, solidifies this identification. Slip.

✿ : Looking at the sequence of images, I can see someone tying a knot around a metal railing/pipe. Let me analyze the progression: 1. The person starts by wrapping a white cord/string around a dark metal pipe. 2. They manipulate the cord through several steps of tying. 3. In the final images, the knot appears to be completed with two ends extending from it. Looking at the final frames, the knot appears to have a compact center with two ends coming out. The way it's tied, with the loops and wraps visible in the middle frames, and the final result showing what appears to be a secure knot that tightens around the pipe, this looks like it could be a clove hitch or similar fixed knot. Examining the tying sequence more closely, particularly how the loops are formed and the cord is threaded through in the middle frames, this creates a knot that would tighten when pulled rather than slip. The final structure with both ends extending suggests a fixed, non-slip connection to the rail, likely a clove hitch or constrictor knot designed to hold securely. Fixed. The sequence of images shows the person tying a knot around a metal railing that involves multiple wraps and tucks. The final result shows a compact, secure knot with both ends extending outward in a way that suggests it will grip the pole tightly when tension is applied. The tying technique, involving loops threaded through each other and tightened against the rail, is characteristic of a fixed knot (such as a constrictor knot or similar binding knot) that will remain secure when pulled from either end, rather than a slip knot that would release when one end is pulled.

☸ : Analyzing knot structure. I need to figure out if pulling one end of the knot will undo it. The sequence shows a short tail near the knot and a long working end, which seems to make a loop and wraps around the standing part. In the final frames, when pulling the long free end, the knot stays around the rail. I need to classify the knot as either slip or fixed based on whether the free end is a bight or the actual end. It appears it's fixed since the tail is threaded through, and pulling tightens it. Fixed.
